Abstract

The incomplete statistics for complex systems is characterized by a so called incompleteness parameter ω which equals unity when information is completely accessible to our treatment. This paper is devoted to the discussion of the incompleteness of accessible information and of the physical signification of ω on the basis of fractal phase space. ω is shown to be proportional to the fractal dimension of the phase space and can be linked to the phase volume expansion and information growth during the scale refining process.

Introduction

A fundamental hypothesis in Boltzmann statistical physics, explicit or not, is that the probability distribution is complete so that $\sum_{i=1}^w p_i = 1$, where w is the number of all the possible states labelled by i and p_i is the probability that the system is at the state i . This is the *complete probability normalization*[1]. In other words, one can treat a complete or asymptotically complete set of states of the system under consideration. This hypothesis of complete statistics implies that the following two conditions must be satisfied. 1) All possible states of the system of interest are well known, which requires a complete knowledge of the dynamics of the system. 2) The known states are accountable and calculable, or in other words, the information is accessible *to us*. Are these two conditions always satisfied?

As the study of complexity advanced, it is revealed that chaotic and fractal behaviors are ubiquitous in nature[2, 3, 4, 5, 6], and that a fractal phase

space in general cannot be completely and exactly exploited. Any calculation based only on the accessible states or the differentiable (integrable) points in this phase space is necessarily incomplete due to the rejected or unknown (singular or unaccessible) points. So the complete descriptions may be satisfactory if and only if these unaccessible points are negligible. If it is not the case, these points should be taken into account or the theoretical descriptions would be aberrant. The question is : how to include the states of a physical system in a theory when they are not accessible to us?

Recently, we have developed a method in this direction[8, 9, 10, 11, 12, 13] : a statistical mechanics based upon the notion of *incomplete information* which has been shown capable of giving *coherently* the Tsallis q -exponential distributions within the nonextensive statistical mechanics (NSM)[8] and, moreover, useful quantum distributions for some systems of correlated electrons[9, 11]. In the present paper, I am presenting some arguments to support the hypothesis of information incompleteness. The physical significations of the incompleteness parameter will be discussed on the basis of fractal phase space.

Incomplete information hypothesis

In the conventional probabilistic science, it is supposed that our ignorance, or information, is *completely* accessible and may be calculated by, e.g., the Hartley formula $I_i = \ln(1/p_i)$ and Shannon information measure $I = \sum_i^w p_i \ln(1/p_i)$ [14, 15], as well as by other generalized information measures[1, 16, 17, 18, 19], under the *harsh* condition that all possible states are accessible to us so that all probabilities sum to one.

However, the hypothesis of *incomplete information* admits simply that a part of our ignorance about complex system may not be accessible to our treatment. It cannot be calculated from probability distributions. In other words, the information calculated by the above mentioned method on the basis of the complete probability normalization may be incomplete because here we only have $\sum_{i=1}^v p_i = \Omega[1]$ where v is the number of the accessible or accountable states and may be greater or smaller than w , the total number of states. Ω represents the incompleteness of the treatment and necessarily linked to the nature of the system. Logically, the origine of this incompleteness may be attributed either to the partial knowledge of the dynamics or to the unaccessible (incalculable) states of the system.

Incomplete information hypothesis has been motivated originally by some fundamental problems encountered in NSM[8, 9, 11, 12, 13, 16, 17, 18, 19].

It replaces the *complete probability normalization* by[8]

$$\sum_{i=1}^v p_i^\omega = 1, \quad (1)$$

where ω is referred to as *incompleteness parameter* which equals unity if the probability distribution is complete[1]. Then on the basis of the Hartley additive information measure $I_i = \ln(1/p_i)$ and the nonadditive generalization of Hartley formula $(I_i)_\omega = \ln_\omega(1/p_i) = \frac{(1/p_i)^{\omega-1}-1}{\omega-1}$, two incomplete entropies $S_{\omega 1} = -k \sum_i p_i^\omega \ln p_i$ and $S_{\omega 2} = k \frac{1-\sum_i p_i}{1-\omega}$ ($\omega \in R$)[8, 9] are deduced. These formalisms not only give in a coherent way the nonextensive incomplete distributions for canonical ensemble $p_i \propto [1 - (1 - \omega)x]^{\omega/(1-\omega)}$ which has been proved very useful for many systems having non-gaussian distributions, they also lead to quantum distributions of which the first results of the applications to correlated electron systems seem quite interesting and promising[9, 11, 13].

With the *incomplete normalization* Eq.(1), the parameter ω can be uniquely related to the incompleteness Ω by

$$\sum_{i=1}^{v-1} p_i^\omega + (\Omega - \sum_{i=1}^{v-1} p_i)^\omega = 1, \quad (2)$$

for any $0 < p_i < 1$, v and Ω . Figure 1 shows the relation between ω and Ω for a given incomplete distribution $\{p_{i=1\dots 5}\} = \{0.1, 0.15, 0.2, 0.25, \Omega - 0.7\}$. We see that, in general, $\Omega > 1$ and $\Omega < 1$ lead to $\omega > 1$ and $\omega < 1$, respectively. If Ω is such that a certain $p_k \rightarrow 1$ among $\{p_{i=1\dots 5}\}$, then $\omega \rightarrow \infty$. If $\Omega \rightarrow 0$, $\omega \rightarrow 0$.

Incomplete normalization in its general form

In general, we should write

$$\sum_{i=1}^v F_\omega(p_i) = 1 \quad (3)$$

in order to normalize incomplete distributions. The function F_ω should depend on the nature of the system and become identity function whenever information is supposed complete ($\Omega = 1$). The arithmetic average of a quantity $\mathbf{x}$ should now be given by

$$\bar{x} = \sum_{i=1}^v F_\omega(p_i) x_i. \quad (4)$$

Figure 1: $\omega - \Omega$ dependence for a given distribution $\{p_{i=1\dots 5}\} = \{0.1, 0.15, 0.2, 0.25, \Omega - 0.7\}$. Note that $\omega \rightarrow \infty$ when $\Omega \rightarrow 1.7$ in this case.

where x_i is the value of $\mathbf{x}$ at the state i .

F_ω may be determined if the information measure and the distribution law are given. For example, with Hartley information measure and exponential distribution, F_ω can be showed to be identity function[9]. In general, by entropy maximization through the functional

$$\delta[\sum_i F_\omega(p_i)I(p_i) + \alpha \sum_i F_\omega(p_i) + \beta \sum_i F_\omega(p_i)x_i] = 0 \quad (5)$$

we get :

$$\frac{\partial \ln F_\omega(p_i)}{\partial p_i} = \frac{\partial I / \partial p_i}{I + \alpha + f_\omega^{-1}(p_i)} \quad (6)$$

or $F_\omega(p_i) = C \exp[\int \frac{\partial I / \partial p_i}{I + \alpha + f_\omega^{-1}(p_i)} dp_i]$ where α and β are the multipliers of Lagrange in Eq.(5), $I(p_i)$ is the information measure, $p_i = f_\omega(x_i)$ the distribution function depending on the parameter ω , and C the normalization constant of F_ω .

Within this frame, we would be able to group many entropies[20] into the family of incomplete entropies if we suppose that the Hartley formula $I_i = \ln(1/p_i)$ holds. For example, the additive entropy proposed by Gorbán and coworkers[21] to generalize Gibbs-Shannon entropy and to obtain

the long and short tail distributions may be considered as the expectation of Hartley information with $F_\alpha(p_i) = p_i - \alpha(p_i + 1)$ for an incomplete description discussed by the authors. In this case, the incompleteness of the description may be given by $\sum_{i=1}^v p_i = \frac{1-\alpha v}{1-\alpha}$. When $\alpha = 0$, the description becomes complete and Gorbun entropy recovers Gibbs-Shannon one. The second example is the entropy due to Burg for solving geophysical problems[22] : $S \propto \sum_i \ln p_i$. To have this, we may put $F_\omega(p_i) = 1/v$ which is a pseudo-equiprobability. Other examples are the entropies of Belis-Guiasu[23] with $F_\omega(p_i) = w_i p_i$ for the study of the information in cybernetic systems and the entropies of Aczel-Daroczy[24] with $F_\omega(p_i) = p_i^\gamma$. So the incomplete normalization seemingly provides a plausible approach to link certain special entropies to elementary information.

About incomplete information in fractal phase space

Through a detailed analysis of the entropy and information on fractal supports, Naschie[25] shows a connection between the information and the topological dimension of some fractal sets. It is also shown that the dynamics of this kind of phase space is quasi-ergodic for $n \geq 4$ where n is the dimension of the set or the number of particles in the fractal phase space of topological dimension d_f [25, 26]. The results of the analysis tell us that the Boltzmann entropy and Gibbs-Shannon entropy for Cantor set increase with increasing capacity dimension given by $d_c^{(n)} = (1/d_f)^{n-1}$ which in turn increases with increasing dimension n of the fractal set. On the other hand, $d_c^{(n)}$ should increase with decreasing topological dimension d_f . This behavior is similar to that of $S_{\omega 1}$ and $S_{\omega 2}$ with respect to the parameter ω [8, 10], which means that ω may have something to do with the topological dimension in fractal phase space.

In what follows, the information on fractal support will be studied from a different angle with the help of the incomplete normalization Eq.(1). First of all, we will show that this kind of power normalization is inevitable for the calculation of fractal information.

An incomplete normalization

For the sake of simplicity, let us consider a phase space in which the trajectory of a complex system forms a self-similar fractal structure, say, Sierpinski carpet (Figure 1). This means that the state point of the system can be found only on the black rectangular segments whose number is $W_k = 8^k$ at k^{th} iteration. Hence the total surface at this stage is given by $S_k = W_k s_k$

Figure 2: A simple model of fractal phase space in Sierpinski carpet which is a self-similar fractal structure generated by dividing, at the first iteration, a full square of side l_0 into 3^2 smaller squares of equal sides of $l_0/3$ and removing the central small square. This procedure will be repeated on every small square at the next iteration and so on. At k^{th} iteration, the side of the squares (black or white) is $l_k = l_0/3^k$ and their number is $W_k = 8^k$, l_0 being the length of the side at 0^{th} iteration. The total surface at k^{th} iteration is $S_k = W_k s_k$ or $W_k s_k / S_k = 1$. The classical probability definition by relative frequency of visits of each point by the system should be modified because the total number of visits (proportional to black surface S_k of the carpet) is no more a finite quantity. (Construction of Sierpinski carpet. First iteration c(1) : removing the central square formed by the straight lines cutting each side into three segments of equal size. Repeat this operation on the 8 remaining squares of equal size and so on.)

where $s_k = l_0/3^k$ is the surface of the segments at k^{th} iteration and l_0 the length of side of the square space at 0^{th} iteration. If the segments do not have same surface, we should write $S_k = \sum_{i=1}^{W_k} s_k(i)$.

Now let us suppose that the density of state is identical everywhere on the segments and that the dynamics in this phase space is quasi-ergodic : *every point on the segments is equally visited*, so that the probability for the system to be in the i^{th} segment may be defined as usual by $p_i = s_k(i)/S_k$. This probability is obviously normalized. The problem is that, as discussed in [2], S_k is an indefinite quantity as $k \rightarrow \infty$ or as the time $t \rightarrow \infty$. So strictly speaking, it can not be used to define exact probability definition or all the probabilities would be null or lose its additivity and normalization according to the countable additivity axiom of probability or total probability axiom which asserts that probabilities can be additive on a set of finite cardinals (number of elements). In addition, S_k is not differentiable and contains inaccessible points. Thus the probability defined above makes no sense.

Alternatively, the probability may be reasonably defined on a integrable and differentiable support, say, the Euclidean space containing the fractal structure. To see how to do this, we write $S_k = l_0^2 (\frac{1}{3^k})^{d-d_f}$ for identical segments or, for segments of variable size,

$$\sum_{i=1}^{W_k} [\frac{s_k(i)}{S_0}]^{d_f/d} = 1 \quad (7)$$

where $S_0 = l_0^d$ (here $d = 2$ for Sierpinski carpet) is a characteristic volume of the fractal structure embedded in a d -dimension Euclidean space, $d_f = \frac{\ln n}{\ln m}$ is the fractal dimension. $n = 8$ is the number of segments replacing a segment of the precedent iteration and $m = 3$ the scale factor of the iterations.

The microcanonical probability distribution at the k^{th} iteration can be defined as

$$p_i = \frac{s_k(i)}{S_0}$$

so that

$$\sum_{i=1}^{W_k} p_i^{d_f/d} = 1.$$

This is just Eq.(1) with $\omega = d_f/d$. The complete probability normalization $\sum_{i=1}^{W_k} p_i = 1$ can be recovered when $d_f = d$.

It should be noticed that, in Eq.(7), the sum over all the W_k segments at the k^{th} iteration does not mean the sum over all possible states of the

system under consideration. This is because that the segment surface $s_k(i)$ does not represent the real number of state points on the segment which, as expected for any self-similar structure, evolves with k just as S_k . So at any given order k , the complete summation over all possible segments is not a complete summation over all possible states. But in any case, whatever is k , Eq.(7) and $\sum_{i=1}^{W_k} p_i^\omega = 1$ always hold for $\omega = d_f/d$.

In this simple case with self-similar fractal structure, the incompleteness of the normalization Eq.(1) is measured by the parameter $\omega = d_f/d$. $d_f > d$ means that the system has more states than W_k , the number of accessible states at given k . If $d_f < d$, the number of states is less than W_k . When $d_f = d$, the summation is complete at any order k , corresponding to complete information calculation.

ω and phase space expansion

Now we will discuss in a detailed way the incompleteness parameter ω and its physical meanings. Let us discuss this still in the case of self-similar fractal phase space.

As discussed in the case of chaotic phase space, $\omega = \ln n/d \ln m$ gives a measure of the incompleteness of the state counting in the d -dimension phase space. $\omega = 1$ means $d_f = d$ or $n = m^d$. In other word, at the k^{th} iteration, a segment of volume s_k is completely covered (replaced) by n segments of volume $s_{k+1} = s_k/m^d$. So the summation over all segments is equivalent to the sum over all possible states, making it possible to calculate complete information.

When $\omega > 1$ (or $\omega < 1$), $n > m^d$ (or $n < m^d$) and s_k is replaced by n segments whose total volume is more (or less) than s_k . So there is expansion (or negative expansion) of state volume when we refine the phase space scale. An estimation of this expansion at each scale refinement can be given by the ratio $r = \frac{ns_{k+1}-s_k}{s_k} = \frac{n}{m^d} - 1 = (\frac{1}{m^d})^{1-\omega} - 1 = (\omega - 1) \frac{(m^d)^{\omega-1}-1}{\omega-1}$. r describes *how much accessible states increase* at each step of the iteration or of the refinement of phase space. The physical content of ω is clear if we note that $\omega > 1$ and $\omega < 1$ correspond to an expansion ($r > 0$) and a negative expansion ($r < 0$), respectively, of the the accessible state volume at each step of the iteration.

When $\omega = 0$, we have $d_f = 0$ and $n = 1$, leading to $r = \frac{1}{m^d} - 1$. The iterate condition $n \geq 1$ means $\omega \geq 0$, as proposed in references [8]. $\omega < 0$ is impossible since it means $d_f < 0$ or $n < 1$ which obviously makes no sense.

We can also write : $\omega - 1 = \ln(r + 1)/\ln(m^d) = \ln(ns_{k+1}/s_k)/\ln(m^d)$, which implies that it is the difference $\omega - 1$ which directly measures the accessible state space expansion through the scale refinement.

ω and information growth

The expansion of the accessible state volume of a system in its phase space during the scale refinement should be interpreted as follows : the extra state points $\Delta = ns_{k+1} - s_k$ acquired at $(k + 1)^{th}$ order iterate are just the number of unaccessible states at k^{th} order with respect to $(k + 1)^{th}$ order. $\Delta > 0$ (or $\Delta < 0$) means that we have counted less (or more) states at k^{th} order than we should have done. Δ contains the *accessible information gain* (AIG) through the $(k + 1)^{th}$ iterate.

To illustrate the relation between this “hidden information” and the parameter ω , let us suppose that *the distribution is scale-invariant*[27]. At the iterate of order k , the average information contained on s_k is given by $I_k = \int_{s_k} p^\omega I(1/p) ds$. At $k + 1$ order, $I_{k+1} = \int_{ns_{k+1}} p^\omega I(1/p) ds$. Hence AIG is just $\Delta I = I_{k+1} - I_k = \int_{(ns_{k+1}-s_k)} p^\omega I(1/p) ds = \sigma_I \Delta$, where $\sigma_I = p^\omega I(1/p)$ is the information density or the average information carried by each state. The relative AIG is given by $\Delta I/I_k = r = (1 - \omega) \frac{(1/m^d)^{1-\omega} - 1}{1-\omega}$ which is independent of scale but dependent on scale changes. For given scaling factor m , the magnitude of ΔI or r increases with increasing difference $|1 - \omega|$. The sign of r (or AIG) was discussed earlier. For given ω , $|\Delta I|$ increases with decreasing scaling. For $\omega = 1$ or $m = 1$, there is no information gain, corresponding to the case of complete information. According to the above discussions, the incompleteness parameter ω may be considered as a measure of the degree of chaos or fractal.

Conclusion

Summing up, we have argued that the information of a complex system we deal with may be incomplete because we only partially know the dynamics of the system or a part of the states of the systems is not accessible to our calculation. The parameterized normalization $\sum_i p_i^\omega = 1$ is justified on fractal support, where the incompleteness parameter ω is shown to be proportional to the fractal dimension of the phase space and can be directly linked to the phase volume expansion and information growth during the scale refining process.

 - [27] Scale invariant probability distribution means that the probability density in a fractal phase space is independent of the iteration order. In the case where any point on the phase space *segments* are equally visited, scale invariance implies that the probability for the system to be on a segment is proportional to the size of the segment, as I supposed in the section VIII when discussing probability normalization in fractal phase space. Scale invariance of probability density is a logical assumption since increasing or decreasing density may lead to infinite probability distributions in fractal phase spaces.
